ABSTRACT

As has been known for over a century, oxygen binding onto hemoglobin is influenced by the activity of hydrogen ions (H⁺), as well as the concentration of carbon dioxide (CO₂). As is also known, the binding of both CO₂ and H⁺ on terminal valine-1 residues is competitive. One-parametric situations of these hemoglobin equilibria at specific levels of H⁺, O₂ or CO₂ are also well described. However, we think interpolating or extrapolating this knowledge into an "empirical" function of three independent variables has not yet been completely satisfactory. We present a model that integrates three orthogonal views of hemoglobin oxygenation, titration, and carbamination at different temperatures. The model is based only on chemical principles, Adair's oxygenation steps and Van't Hoff equation of temperature dependences. Our model fits the measurements of the Haldane coefficient and CO₂ hemoglobin saturation. It also fits the oxygen dissociation curve influenced by simultaneous changes in H⁺, CO₂ and O₂, which makes it a strong candidate for integration into more complex models of blood acid-base with gas transport, where any combination of mentioned substances can appear.

Keywords: Acid-Base Equilibrium; Blood Gas Analysis; Carboxyhemoglobin; Hemoglobin A; Oxyhemoglobins

INTRODUCTION

Human hemoglobin A is one of the most extensively studied protein macromolecules. The composition and 3D conformation of both α and β chains is known [1, 2] and the binding of O_2 , H^+ and 2,3-DPG has been described [2, 3]. Since the 1930s it has generally been believed that CO_2 binding to Hb occurs by carbamination of the amino-terminus, forming a carboxylate compound [4-6]. This hemoglobin carbamination was verified by Morrow et al. [7], who used nuclear magnetic resonance of $^{13}CO_2$ to find its exact binding sites at valine-1. The shift of titration between oxygenated and deoxygenated forms is also well known. Called the Bohr or Haldane effect [8-10], it is caused by the same valine-1 side and by more than ten other acid-base residues [2, 11].

The most common descriptions of the hemoglobin oxygen dissociation curve (ODC) are the allosteric models [12, 13], the model based on Hill equation [14, 15], and Adair's four-step model [16]. Some of the ODC models [15, 17, 18] also include the effects of varying pH and CO_2 concentration. However, these models operate only with interpolation or extrapolation of ODC from normal pH or normal pCO_2 and do not take into account the chemical dependences between titration [8] and carbamination [19]. They fail when both pH and CO_2 are not at normal values, especially in the alkaline pH range.

Based on these findings, we propose a hemoglobin binding equilibrium model that starts with a description of hemoglobin-oxygen dissociation using a slightly modified version of Adair's approach [16]. We continue by describing the relationship between CO_2 and H^+ as competitive inhibition in the amino group of terminal valine-1 residue on each chain (suffixes z and c), which is in accordance with the known facts [4, 6, 20]. Finally, we lump all other acid-base side chain residues in a hemoglobin subunit into one Bohr proton-binding site of the side chain residues. These are denoted by the suffix h in the article.

METHODS

The model is built in Mathematica 9.0 (Wolfram, Champaign, IL) and also in Dymola FD01 2014 (Dassault Systemes, Paris, France) as an example of chemical package in open-source Modelica library Physiolib 2.2.0 [21, 22] according to the model structure defined in the following section. The model contains only physiological parameters such as gas solubilities and dissociation coefficients of defined reactions. The unknown parameters are fitted to the data of Siggaard-Andersen [23], Bauer and Schröder [24], Severinghaus [18], Matthew et al. [1] and Reeves [25] using Mathematica function FindFit and also using parameter estimation method suggested by Kulhanek et al. [26].

Free dissolved concentrations of $[O_2]$ and $[CO_2]$ in red blood cells are calculated from gas partial pressures using Henry's law ($[O_2]=\alpha_{O_2}\cdot pO_2$ and $[CO_2]=\alpha_{CO_2}\cdot pCO_2$) with solubility coefficients $\alpha_{O_2}=1.005\cdot 10^{-5}\text{ mol}\cdot\text{m}^{-3}\cdot\text{Pa}^{-1}$ measured at 38 °C by Sendroy et al. [27], and $\alpha_{CO_2}=2.3\cdot 10^{-4}\text{ mol}\cdot\text{m}^{-3}\cdot\text{Pa}^{-1}$ at 37 °C, as proposed by Maas et al. [28]. These solubilities are slightly different from solubilities in pure water or in plasma because of the effects of salts and proteins inside erythrocyte [27].

MODEL STRUCTURE

The model is built upon several simplifying assumptions. Firstly, each of four hemoglobin tetramer subunits is treated as identical, even though (slight) differences are known to exist between α and β subunits. Secondly, CO_2 or H^+ binding is supposed not to affect the CO_2 or H^+ affinities in the other three subunits. Thus, the interaction between the subunits is modeled purely

through the varying affinities of oxygen in each oxygenation step. The third simplifying assumption has already been mentioned; it is lumping all Bohr proton binding sites of subunit into two (first for the valine-1 amino-terminus and second for the side chains residues), a simplification first suggested by Antonini [29].

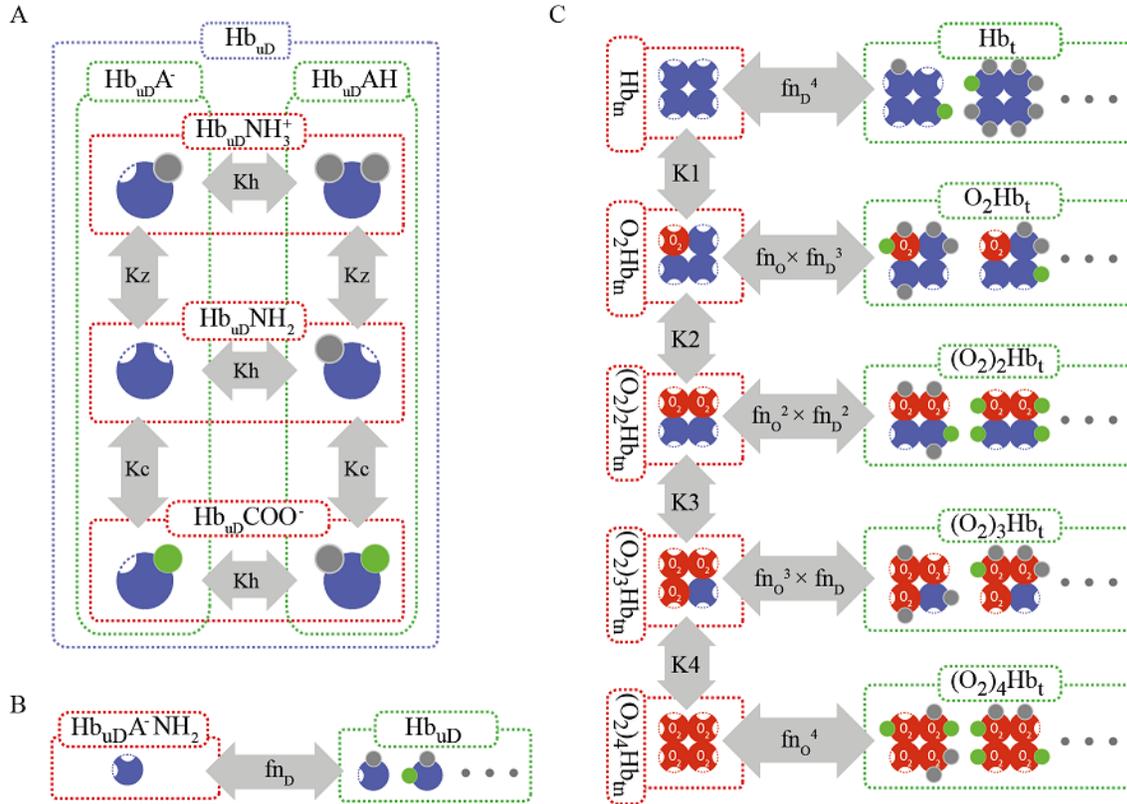

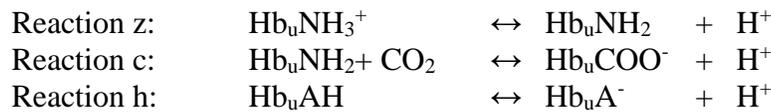

Figure 1, Schema of hemoglobin calculation

A) Possible forms of deoxyhemoglobin subunit (the blue circles). The gray circles represent hydrogen ions, and the green circles represent carbon dioxide. The arrows with dissociation coefficients represent the reactions z, c and h. B) Schema of chemical speciation of deoxyhemoglobin subunit. C) Schema of chemical speciation and Adair's oxygenation steps of hemoglobin tetramer.

Model structure of hemoglobin subunit

The three reactions that participate in the Bohr and Haldane effect of each subunit are as follows:

where the reactions z and c are competitive on the valine-1 amino-terminus, and the reaction h is independent of z or c.

The chemical equilibrium equations of these three reactions are Eq.1-3, where K_x is the equilibrium dissociation coefficients of the reaction x (i.e., z, c or h).

$$\text{Reaction z:} \quad K_z = \frac{[Hb_uNH_2] * aH^+}{[Hb_uNH_3^+]} \quad (1)$$

$$\text{Reaction c:} \quad K_c = \frac{[Hb_uCOO^-] * aH^+}{[CO_2][Hb_uNH_2]} \quad (2)$$

$$\text{Reaction h:} \quad K_h = \frac{[Hb_uA^-] * aH^+}{[Hb_uAH]} \quad (3)$$

These dissociation coefficients are different between oxy and deoxy subunits, which are distinguished by the subscripts O and D in the following text. They can be also written in their logarithmic form, where \mathbf{pK}_x means $-\log_{10}(K_x)$. Thus, for instance, \mathbf{pK}_{zO} denotes the equilibrium coefficient of the reaction z for the oxy form of the hemoglobin subunit. Similar notation is used for describing the activity of hydrogen ions (acidity), where $\mathbf{pH} = -\log_{10}(aH^+)$.

Using Eq.1-3 it is possible to express fractions for deoxy and oxy subunits. We label these fractions as follows: Hb_uNH_2 fractions are called \mathbf{f}_{zCD} (\mathbf{f}_{zCO}), Hb_uA^- fractions \mathbf{f}_{hD} (\mathbf{f}_{hO}), $Hb_uA^-NH_2$ fractions \mathbf{fn}_D (\mathbf{fn}_O) and Hb_uCOO^- fractions \mathbf{sCO}_{2D} (\mathbf{sCO}_{2O}) as in Eq. 4-7. The selection of form $Hb_uA^-NH_2$ from the division into Hb_uNH_2 and Hb_uA^- is also illustrated in Fig. 1A, B.

$$f_{zCD} = \frac{[Hb_{uD}NH_2]}{[Hb_{uD}]} = \frac{1}{1 + 10^{\mathbf{pK}_{zD} - \mathbf{pH}} + [CO_2]10^{\mathbf{pH} - \mathbf{pK}_{cD}}} \quad (4)$$

$$f_{hD} = \frac{[Hb_{uD}A^-]}{[Hb_{uD}]} = \frac{1}{10^{\mathbf{pK}_{hD} - \mathbf{pH}} + 1} \quad (5)$$

$$fn_D = \frac{[Hb_{uD}A^-NH_2]}{[Hb_{uD}]} = f_{zCD} \times f_{hD} \quad (6)$$

$$sCO_{2D} = \frac{[Hb_{uD}COO^-]}{[Hb_{uD}]} = 10^{\mathbf{pH} - \mathbf{pK}_{cD}} f_{zCD} [CO_2] \quad (7)$$

We define a titration shift as the amount of acid that must be added to achieve the same pH after full deoxygenation of the hemoglobin subunit. This change of subunit charge during deoxygenation (by the Bohr protons) is also called Haldane coefficient ΔH^+ . The coefficient can be divided into contributions of the previously mentioned reactions ΔH_h^+ , ΔH_z^+ and ΔH_c^+ , as is algebraically expressed by Eq. 8-11.

$$\Delta H_h^+ = - \frac{[Hb_{uD}A^-] - [Hb_{uO}A^-]}{[Hb_u]} = -(f_{hD} - f_{hO}) \quad (8)$$

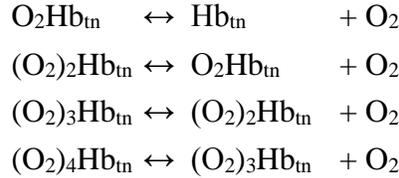

$$\Delta H_z^+ = \frac{[Hb_{uD}NH_3^+] - [Hb_{uO}NH_3^+]}{[Hb_u]} = \left(\frac{10^{\mathbf{pK}_{zD}}}{10^{\mathbf{pH}}} f_{zCD} - \frac{10^{\mathbf{pK}_{zO}}}{10^{\mathbf{pH}}} f_{zCO} \right) \quad (9)$$

$$\Delta H_c^+ = -\frac{[Hb_{uD}COO^-] - [Hb_{uO}COO^-]}{[Hb_u]} = -(sCO_{2D} - sCO_{2O}) \quad (10)$$

$$\Delta H^+ = \Delta H_z^+ + \Delta H_c^+ + \Delta H_h^+ \quad (11)$$

Model structure of hemoglobin tetramer

The speciation of the hemoglobin tetramer molecule can be considered at various levels of detail; the one chosen as appropriate in our approach is indicated in Fig. 1C. The possible forms include different combinations of oxygenated and deoxygenated hemes, protonated and deprotonated oxygen-linked acid groups, and free or carboxylated amino endings of each chain. Yet because of the law of detailed balance in equilibrium [30], it is not necessary to calculate all reactions between these forms. As a result, only four oxygenation reactions need be selected for the calculation. This is done in accordance with Fig. 1C, by selecting a tetramer form $(O_2)_iHb_{tn}$ composed only of four subunits in the form $Hb_uA'NH_2$ (H^+ and CO_2 free), and modeling oxygen binding to these forms with Adair-type coefficients of the following reactions:

where dissociation coefficients are defined by Eq.12, which are also represented by vertical arrows at Fig. 1C.

$$K_i = \frac{[(O_2)_{i-1}Hb_{tn}] \cdot [O_2]}{[(O_2)_iHb_{tn}]} \quad (12)$$

For the next calculation, all forms can be expressed as a fraction of the deoxy-tetramer form $(O_2)_0Hb_{tn}$, as shown in Eq. 13.

$$[(O_2)_iHb_{tn}] = \frac{[(O_2)_0Hb_{tn}] \cdot [O_2]^i}{\prod_{j=1}^i K_j} \quad (13)$$

Let us move the attention from specific forms of Hb_{tn} to the description of the equilibrium within the whole group of Hbt. Looking at Fig. 1C, one can see that for each oxygenation step we can calculate the equilibrium in each horizontal line using Eq. 14.

$$[(O_2)_iHb_t] \cdot f n_D^{4-i} \cdot f n_O^i = [(O_2)_iHb_{tn}] \quad (14)$$

The CO_2 - and pH-dependent oxygen saturation equation in the Adair style (Eq. 15) is algebraically derived from Eq. 13-14, where $a_i = 1/(\prod_{j=1}^i K_j)$ and $x = (f n_D(pH, [CO_2])/f n_O(pH, [CO_2])) * [O_2]$.

$$sO_2 = \frac{a_1 x + 2 a_2 x^2 + 3 a_3 x^3 + 4 a_4 x^4}{4 + 4 a_1 x + 4 a_2 x^2 + 4 a_3 x^3 + 4 a_4 x^4} \quad (15)$$

Hemoglobin saturation with CO₂ (sCO₂) is calculated separately in oxygenated and deoxygenated subunits forms (sCO_{2O} and sCO_{2D}) using Eq. 16.

$$sCO_2 = sO_2 \cdot sCO_{2O} + (1 - sO_2) \cdot sCO_{2D} \quad (16)$$

Finally, the shift of titration after deoxygenation and decarbamination of the hemoglobin subunit can be expressed by Eq. 17.

$$dTH = sO_2 \cdot \Delta H^+ + sCO_{2D} + \frac{sCO_{2D}}{1 + 10^{pH - pKzD}} \quad (17)$$

Temperature dependences

The temperature dependences are integrated using the Van't Hoff equation (Eq. 18), where $R=8.314 \text{ J.K}^{-1}.\text{mol}^{-1}$ is gas constant, ΔH^θ is the standard enthalpy change as an amount of heat consumed by a reaction changing one mole of substrates to products, and K_2 and K_1 are Henry's coefficients of solution or the dissociation coefficient of the chemical reaction at temperature T_2 and T_1 (expressed in Kelvin).

$$\ln \left(\frac{K_2}{K_1} \right) = \frac{-\Delta H^\theta}{R} \left(\frac{1}{T_2} - \frac{1}{T_1} \right) \quad (18)$$

RESULTS

The Adair's coefficients are fitted to the collection of ODC measurements by Severinghaus [18] at $pCO_2=0 \text{ Pa}$ and $pH_p=7.4$, see Fig. 2A and Table I. The dissociation coefficients of carboxylation are determined in close agreement with Bauer and Schröder using their data [24]; the resulting fit can be seen in Fig. 2B, the coefficients are in Table II. The lumped acid dissociation coefficients for the side-chains $pKhD$ and $pKhO$ are estimated by optimization of Siggaard-Andersen's data [23] at $DPG/Hbt=0.84$, $pH=6.5$ to 8.0 and 37°C ; the resulting fit can be seen in Fig. 2C, and the coefficients complete Table II.

Table I

Estimated form-specific Adair's coefficients [mol.m^{-3}] at 37°C			
K_1	K_2	K_3	K_4
0.0121	0.0117	0.0871	0.000386

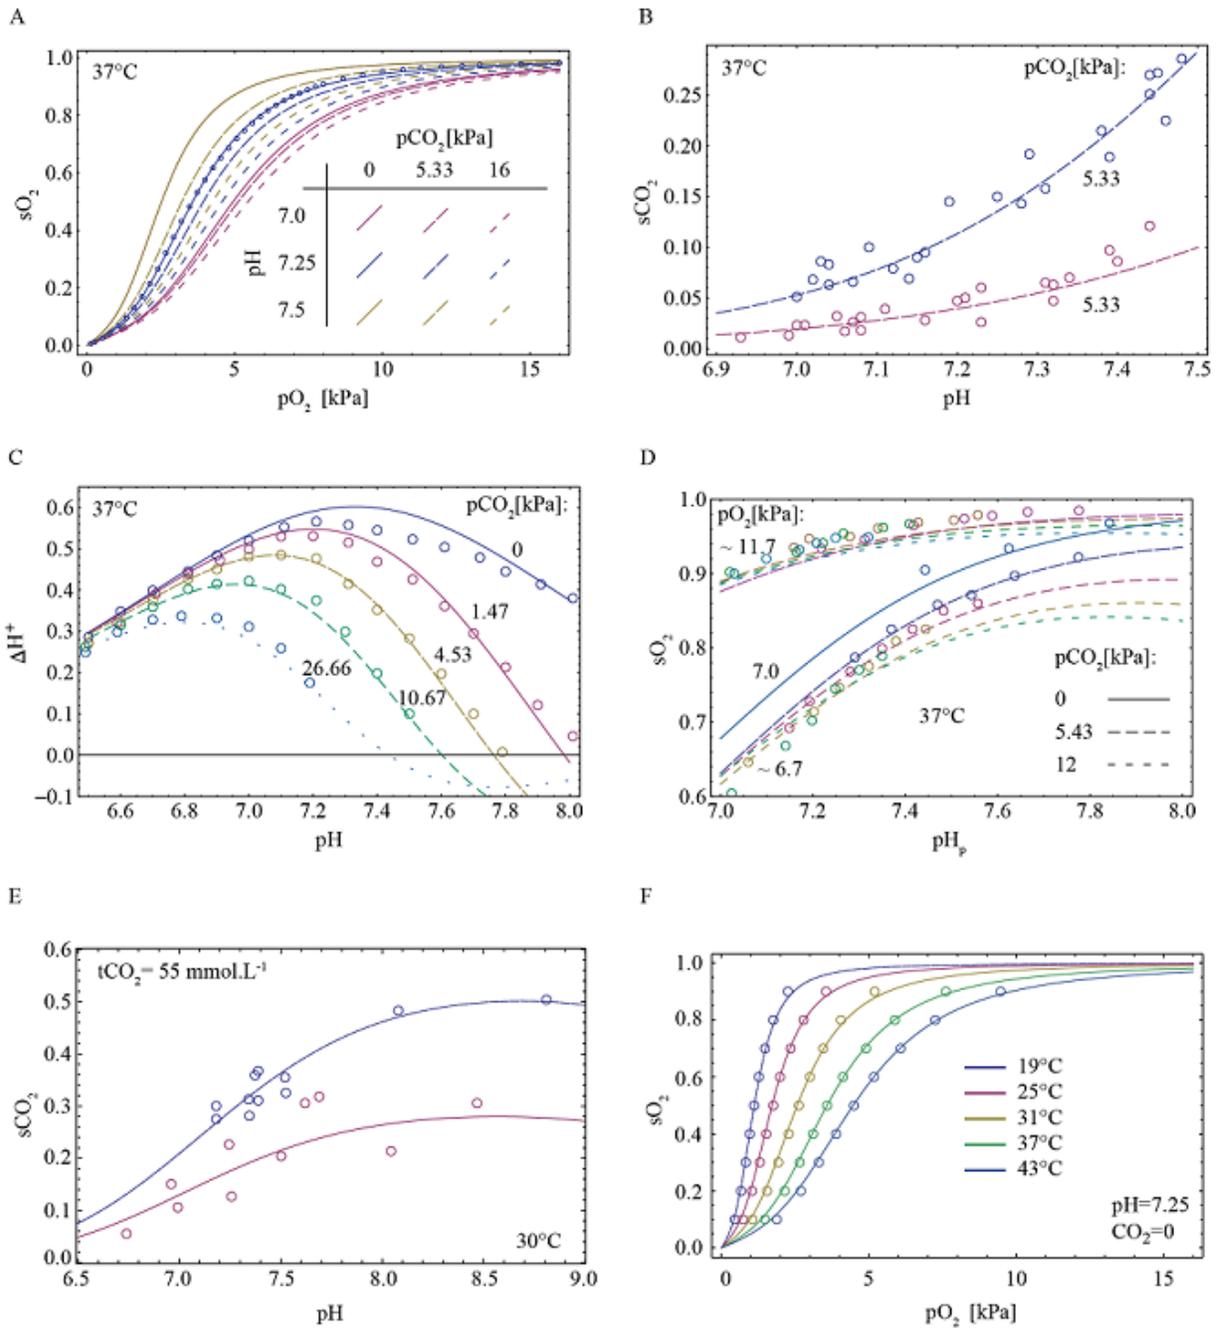

Figure 2, Model curves and measured data points

A) Points are from Severinghaus's oxygen dissociation curve collection [18] at $p\text{CO}_2=0$ Pa, erythrocyte intracellular $\text{pH}=7.2$ and temperature 37°C . Lines are $s\text{O}_2$ defined by Eq. 15 B) Carboxylation of hemoglobin measured and estimated by Bauer and Schröder [24]. The lines (Eq. 7) are $s\text{CO}_2\text{D}$ and $s\text{CO}_2\text{O}$ at $p\text{CO}_2=5.33$ kPa. C) Bohr protons released during oxygenation of one hemoglobin subunit. Dots are data measured by Siggaard-Andersen [23] in erythrolysate at 37°C , $\text{DPG}/\text{Hbt} = 0.84$. Lines are calculated from Eq. 11 using data from Table II. From top to bottom data are plotted for different $p\text{CO}_2=0$ kPa, 1.47 kPa, 4.53 kPa, 10.67 kPa and 26.66 kPa. D) Naeraa et al.'s [29] oxygen saturation data comparison. The two groups of lines (Eq. 15) are determined mainly by $p\text{O}_2$ around 6.7 kPa and 11.7 kPa. The small nuances in each group are caused by different $p\text{CO}_2$ changed from 0 kPa to 12 kPa. E) Matthew et al.'s [1] carbamination data measured at 30°C with constant content of all carbonates 55 $\text{mmol}\cdot\text{L}^{-1}$. Fitted dissociation constants, which determine the lines, are used to estimate enthalpies of their reactions to be consistent with Bauer and Schröder [24]. F) Reeves [32] oxygen saturation data at different temperatures. Enthalpies of reaction h and specific Adair oxygenation step enthalpy is estimated (lines) to fit the data (circles).

We concluded that the model also describes the ODC shifts by comparing with Naerea et al.'s [31] oxygen saturation measurements at different plasma pH and CO₂ levels, see Fig. 2D. The recalculation of data from plasma pH_p to intracellular erythrocyte pH uses the equation $\text{pH}=7.2464+0.796(\text{pH}_p-7.4)$, as presented by Siggaard-Andersen and Salling [32].

Table II

Estimated acid dissociation coefficients at 37°C		
<i>reaction z</i>	<i>reaction c</i>	<i>reaction h</i>
$\text{pK}_{zD}=7.73$	$\text{pK}_{cD}=4.54$	$\text{pK}_{hD}=7.52$
$\text{pK}_{zO}=7.25$	$\text{pK}_{cO}=5.35$	$\text{pK}_{hO}=6.89$

The gas solubility as Henry's coefficient at different temperatures can be recalculated using the enthalpy of gas solution (-14 kJ.mol⁻¹ for O₂, and -20 kJ.mol⁻¹ for CO₂ [33]). If we assume that the examined hemoglobin of Matthew [1] is at compatible conditions, but at a temperature of 30°C with $\text{pK}_{zD}=7.53$, $\text{pK}_{zO}=7.28$, $\text{pK}_{cD}=4.77$ and $\text{pK}_{cO}=5.20$ as plotted in Fig. 2E, then the enthalpies of these reactions are -51, 8, 59 and -41 kJ.mol⁻¹. The heat of oxygenation unaffected by oxygen heat of solution, by carbon dioxide and by Bohr protons was measured by Atha and Ackers [34] as 59 kJ.mol⁻¹. Using this value for each Adair oxygenation step it is possible to optimize other enthalpies to fit the Reeves data [25], measured at 19-43°C. Resulting as the enthalpies 59 kJ.mol⁻¹ of deoxy and -127 kJ.mol⁻¹ of oxy version of reaction *h* to reach ODCs curves plotted in Fig. 2F.

DISCUSSION

Having a precise quantitative description of hemoglobin behavior is a crucial aspect in describing the behavior of whole blood, which has numerous uses in medicine today. It is important in areas such as blood gas analysis [15, 35], the building of complex models [36], simulation for teaching purposes [37], or rebreathing-based methods for cardiac output estimation, which represent a more specific use [38]. For instance, the precision of the latter methods is crucially dependent on the exact calculation of the total amount of carbon dioxide in blood for various (abnormal) patient conditions, as has been recently pointed out [39].

This model offers a precise description of various phenomena that take place with hemoglobin, based on relatively simple starting points, such as competitive binding of H⁺ and CO₂ at valine-1 amino terminus or the law of detailed balance [30]. Even with a simple structure, it offers a remarkably good fit to the data of hemoglobin oxygenation, titration, and carbamination at different temperatures, as shown in Fig. 2A-E. These can be calculated with any combination of oxygen, carbon dioxide and hydrogen ions defined as open system (lungs), where the partial pressures are equilibrated, and also in a closed system (tissues), where mass conservation laws and the total amount of substances take place, as was also modeled by Rees and Andreassen [40], among others.

The results of our model (Fig. 2A-E) show strong nonlinear dependences between variables, which is in agreement with the known data [1, 23-25, 41]. Looking at Fig. A, one can compare sets of ODCs, where each color represents a different pH. Various curves of each color represent

ODCs for various levels of $p\text{CO}_2$ for a given pH. As can be seen, the effect of $p\text{CO}_2$ on the ODC is stronger at high (alkaline) pH, which is in agreement with the data [23]. Similarly, one can compare the curves within the sets of solid or dashed lines, where each set represents dissociation curves for various values of pH at a given level of $p\text{CO}_2$. The variation between the curves of each line type represents the Bohr effect for the given level of CO_2 , this effect can also be appreciated from data of Fig. 2C, which shows the average amount of released H^+ upon oxygenation of one hemoglobin subunit.

The model uses enthalpies to calculate temperature dependences of hemoglobin behavior (Fig. 2F,E), which allows examination of the heat transfers during single chemical processes. For instance, binding of aqueous oxygen onto hemoglobin produces 30-40 kJ/mol of heat [42-45], and the same amount of heat is consumed by deoxygenation process in metabolically active tissues, thus helping to cool them down. When the hemoglobin model is used in the standard conditions of a large-scale HumMod model [36], the resulting heat transfer due to the exothermy of the hemoglobin oxygen reaction is 4-7% of the total heat produced by muscle, which is in agreement with experimental results [42, 44, 45]. It is interesting to note that this heat transfer occurs without any increase in blood temperature.

The integration of chemical processes in a macromolecule requires a precise view into their underlying principles. Some physiologists use the elementary chemical equations [40], but do not implement the principle of detailed balance [30]. Other physiologists make empirically-based equations with a raw linear gradient approximation of possible combinations of model values [15]. We feel that it is almost impossible to see the problem as this type of black-box function with more than two inputs. Instead, it is better to have an integrated model of oxygenation, titration and carbamination.

Today, allosteric hemoglobin oxygenation models do exist that seem more in agreement with the structural knowledge of hemoglobin [12, 46-48]. These models take into account two or more structurally different forms: relaxed and tensed. However, these models have so far been limited to hemoglobin oxygenation only. Our Adair-based model can explain not only oxygen and carbon dioxide saturation, but also their cooperation with acid-base buffering properties of hemoglobin. All three of these connected phenomena fit to measured data in physiological ranges. The limitation of our model is that it does not contain the tetramer space conformations. In future the model could be extended with dependences on electrolytes such as chloride, 2,3-bisphosphoglycerate or other organic phosphates and their binding reactions, as many research studies show these interactions [49-52]. The oxygenation could also be improved for the allosteric models [12, 48], assuming that oxy-reactions are almost in relaxed forms and deoxy-reactions are in tensed forms. The next extension of this model could be performed by the integration of an intracellular red cell environment to calculate with phosphate acid-base buffers, and finally the membrane changes with blood plasma, where the chloride shift reaches a Gibbs-Donnan equilibrium and establishes chloride, bicarbonate and hydrogen ion activity ratios. Having an integrated model of blood gases and acid-base is crucial if we want the precise computational algorithms of the current state of a patient. These calculations could be used, for example, inside the next generation of medical devices to estimate not only blood properties, but also the connected properties of circulation [38] or metabolic functions [40].

In this article, we present a hemoglobin model that integrates O_2 , CO_2 and H^+ binding. The model is not just empirical, but is based on sound theoretical principles, such as the competitive binding of CO_2 and H^+ on the valine-1 NH_2 terminus, the Bohr and Haldane effect [9, 53] and on the principle of detailed balance. The principle of detailed balance is used for the first time in the

Adair type of model, offering mass and energy conservation principles, and accumulates substances and heat inside hemoglobin forms, which is very useful for integration in higher-scale dynamic models.

LIST OF ABBREVIATIONS

ODC	hemoglobin oxygen dissociation curve
2,3-DPG	2,3-diphosphoglycerate
[X]	molar concentration of X in mol.m ⁻³
aH ⁺	activity of hydrogen ions, where pH=-log ₁₀ (aH ⁺)
αO ₂	O ₂ solubility in mol.m ⁻³ .Pa ⁻¹
αCO ₂	CO ₂ solubility in mol.m ⁻³ .Pa ⁻¹
pO ₂	partial pressure of O ₂ in Pa
pCO ₂	partial pressure of CO ₂ in Pa
Hb _u	hemoglobin alpha or beta subunit
Hb _{uD}	deoxygenated Hb _u
Hb _{uO}	oxygenated Hb _u
Hb _u NH ₃ ⁺	Hb _u with protonated N-terminus
Hb _{uD} NH ₃ ⁺	Hb _{uD} with protonated N-terminus
Hb _{uO} NH ₃ ⁺	Hb _{uO} with protonated N-terminus
Hb _u NH ₂	Hb _u with -NH ₂ form of N-terminus
Hb _{uD} NH ₂	Hb _{uD} with -NH ₂ form of N-terminus
Hb _{uO} NH ₂	Hb _{uO} with -NH ₂ form of N-terminus
Hb _u COO ⁻	Hb _u with carboxylated N-terminus
Hb _{uD} COO ⁻	Hb _{uD} with carboxylated N-terminus
Hb _{uO} COO ⁻	Hb _{uO} with carboxylated N-terminus
Hb _u AH	Hb _u with protonated side-chains
Hb _{uD} AH	Hb _{uD} with protonated side-chains
Hb _{uO} AH	Hb _{uO} with protonated side-chains
Hb _u A ⁻	Hb _u with deprotonated side-chains
Hb _{uD} A ⁻	Hb _{uD} with deprotonated side-chains
Hb _{uO} A ⁻	Hb _{uO} with deprotonated side-chains
Hb _u A ⁻ NH ₂	selected normalized form of Hb _u with deprotonated side-chains and -NH ₂ form of N-terminus
Hb _{uD} A ⁻ NH ₂	deoxygenated form of Hb _u A ⁻ NH ₂
Hb _{uO} A ⁻ NH ₂	oxygenated form of Hb _u A ⁻ NH ₂
f _{nD}	fraction of Hb _{uD} A ⁻ NH ₂ from Hb _{uD}
f _{nO}	fraction of Hb _{uO} A ⁻ NH ₂ from Hb _{uO}
f _{zCD}	fraction of Hb _{uD} NH ₂ form Hb _{uD}
f _{zCO}	fraction of Hb _{uO} NH ₂ form Hb _{uO}
f _{hD}	fraction of Hb _{uD} A ⁻ form Hb _{uD}
f _{hO}	fraction of Hb _{uO} A ⁻ form Hb _{uO}
ΔH _h ⁺	change of valence (charge) on side-chains during deoxygenation per one Hb _u
ΔH _z ⁺	protonation of -NH ₂ form of N-terminus during deoxygenation per one Hb _u
ΔH _c ⁺	decarboxylation of carboxylated N-terminus during deoxygenation per one Hb _u
ΔH ⁺	Haldane coefficient per hemoglobin subunit
Hb _t	hemoglobin tetramer without bound O ₂ molecules
(O ₂) _i Hb _t	hemoglobin tetramer with the number of <i>i</i> bound O ₂ molecules

$(\text{O}_2)_i\text{Hb}_{\text{tn}}$	hemoglobin tetramer composed only of $\text{Hb}_u\text{A}^-\text{NH}_2$ subunit forms with the number of i bound O_2 molecules
$s\text{O}_2$	O_2 saturation of hemoglobin
$s\text{CO}_{2\text{D}}$	CO_2 saturation of deoxyhemoglobin
$s\text{CO}_{2\text{O}}$	CO_2 saturation of oxyhemoglobin
$s\text{CO}_2$	CO_2 saturation of hemoglobin
$t\text{CO}_2$	total concentration of $\text{CO}_2 = \text{free dissolved } \text{CO}_2 + \text{HCO}_3^- + \text{CO}_3^{2-} + \text{Hb}_u\text{COO}^-$
$d\text{TH}$	shift of titration curve, which equals how many mols of titrant must be added to one mol of hemoglobin subunit to reach the same pH of the base (O_2 - and CO_2 -free) titration curve
pH	acidity/basicity of hemoglobin solution (e.g. inside erythrocytes)
pH_p	pH in plasma (e.g. acidity/basicity of blood)
